Abstract—The objective of this work is to show how to control the electric power systems of a vehicle in such a manner that their power flows should be optimized in the sense of energy efficiency. As will be seen, the control problem considered in this work can be formulated as an optimization problem in the presence of several constraints. A systematic approach based on optimal control will be adopted to design the energy management strategies. Then, by means of these strategies, the electric energy will be generated and stored in the most appropriate manner so that the overall energy consumption and eventually the pollutant emissions can be minimized for a given driving cycle. To this end, both non-causal optimization method using the knowledge of the entire driving cycle and causal one are developed for two case studies with different structures of energy storage system. These strategies are then evaluated in an advanced simulation environment to point out their effectiveness.

Index Terms—Energy management system, vehicular electric power system, battery and supercapacitor, Pontryagin's minimum principle, state constraints.

1. Introduction

Over the years, the demand of electric power consumption in conventional vehicle has become more and more important. This is due to the fact that automotive customers are more and more demanding in terms of performance, comfort and safety for their new vehicles. Hence, the number of auxiliary electric-powered devices has been constantly increased in modern vehicles, e.g. active

28 suspension, electric brakes, catalyst heaters, etc. This increasing demand tends to double or triple the
29 current vehicle electric load [1]. Besides improving the efficiency of the electric components, an
30 effective energy management strategy (EMS) is also crucial to minimize the overall energy
31 consumption of the vehicle.

32 In this work, the key feature of the studied vehicle consists in the presence of an electrical
33 supercharger (eSC) in the turbocharged air system of the spark-ignition (SI) engine. This device aims
34 at assisting the main turbocharger to reduce the effects of "turbo lag", i.e. slow engine torque
35 dynamics and lack of torque at low speeds. As a consequent, the drivability is significantly improved.
36 The energy consumption of the eSC is provided by the vehicular electric power system. To this end,
37 the vehicle is equipped with an advanced alternator which is controlled in power. Note that this
38 alternator is directly coupled to the vehicle primary shaft; therefore, the engine operating point can be
39 shifted by controlling the alternator output power. This fact offers one degree of freedom for energy
40 optimization as in the case of classical parallel hybrid electric vehicles. However, this small capacity
41 alternator is exclusively used to generate the energy for the electric power system and cannot assist
42 the internal combustion engine (ICE) to propel the vehicle. Note also that the considered alternator
43 can also recover the kinetic and potential energy during the regenerative braking phases. This "free
44 energy" is then stored in the energy storage system (ESS) and will be used later in appropriate ways.

45 From the above remarks, it is clear that the energy management becomes very attractive to
46 improve the overall energy efficiency of the studied vehicle. Because of industrial specifications, the
47 developed strategies have to satisfy several objectives. First, they can offer a global optimal solution
48 when the driving conditions are perfectly known in advance, i.e. *offline situations*. Second, their
49 adaptations for real-world driving situations (i.e. *online situations*) are straightforward and the
50 resulting causal strategies behave closely as the global optimal ones. Third, the developed strategies
51 must be simple to be implementable with limited computation and memory resources. Fourth, the
52 strategies are based on a systematic approach so that they can be applicable to a large spectrum of

53 component dimension without the need for extensive calibration. For all these reasons, the developed
54 EMSs will be based on an optimal control approach using physical component models of the vehicle.

55 Because of the relevance to this work, a brief overview concerning the optimal based energy
56 management issue for hybrid electric vehicle [2,3] will be provided. In automotive framework, there
57 are mainly two methods based on optimal control theory which may offer a globally optimal result in
58 offline situations: Dynamic Programming (DP) [4] and Pontryagin's Minimum Principle (PMP) [5].
59 DP-based strategies are known to be very costly in terms of computation. Numerous efforts have
60 been devoted to reduce the computation time [6]. These strategies are often used for offline purposes
61 (performance evaluation, component sizing) [7]. Some adapted online versions can be found in
62 [8,9,10]. Concerning the strategies based on PMP, their optimum could not be global as in the case of
63 DP since the PMP only provides necessary optimality conditions. However, they are much more
64 computationally efficient and the online adaptation is more straightforward. This is the main reason
65 why we only deal with PMP approach in this work. In the literature, many results exist on PMP-
66 based strategies [11,12] or the related Equivalent Consumption Minimization Strategies (ECMS)
67 [13,14]. Besides optimal control based approaches, some rule-based methods for energy management
68 can also be found in literature, see [15,16,17] and references therein.

69 The main focus of this paper is to propose a systematic approach to design the energy
70 management strategies that optimize the power flow of the vehicular electric power system. To this
71 end, both online and offline strategies are considered. Thank to these optimal based EMSs, the
72 overall energy consumption of the vehicle is minimized under all driving situations. A preliminary
73 study on the choice of the structure of energy storage system was carried out by our industrial
74 partners. From that, two case studies of electric power system with the same vehicle architecture will
75 be considered. These choices are mainly due to the acceptable cost especially for the energy storage
76 devices compared to conventional hybrid vehicles. The first case study is as in a conventional vehicle
77 where only the battery is used to provide all onboard electric consumption and to make the electric

78 power system more robust against peak-power demands. In this case, the EMS will exploit the
79 freedom that the battery offers to the alternator in deciding the moment to generate electric power.
80 This degree of freedom is generally not used [10]. For the second case study, a hybrid storage system
81 combining a supercapacitor [18] together with a battery will be used. Such a hybrid storage system
82 has been widely used in automotive industry since it has both the high energy density of the battery
83 and the high power density of the supercapacitor [19]. The supercapacitor aims at providing high
84 currents during hard transition phases to protect the battery from fatal damages caused by over-
85 discharge [2]. The supercapacitor is also used to store energy from regenerative braking and to
86 reduce the battery size [19]. As will be seen, battery/supercapacitor hybrid energy storage system is
87 more flexible in terms of optimization than the first one since it offers two degrees of freedom for
88 EMS. However the electric structure and the control design are more complex than the first case.

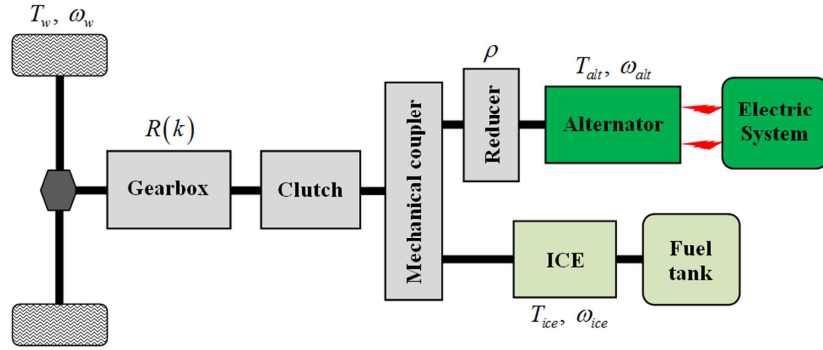

89 In this work, we assume that the state constraints concerning the battery are not critical for
90 optimization problem since it can be oversized. However, the supercapacitor may quickly charge and
91 discharge due to its low specific energy compared to the battery [15]. Hence, the state constraints of
92 the supercapacitor should be taken into account. To this end, a new form of penalty function will be
93 proposed by introducing a dummy variable in the expression of the Hamiltonian. The strategies
94 developed in this work are simple to implement, efficient in terms of fuel reduction and of
95 computation times. They can be directly applied to parallel hybrid electric vehicles, and the
96 formulation can be easily generalized to a large family of hybrid vehicles.

97 The paper is organized as follows. Section 2 first presents the studied vehicle structure with its
98 two different electric power systems. Then, the models of some vehicle components used for control
99 purpose are provided. In Section 3, the optimal control problems are formulated for both case studies
100 and the Pontryagin's Minimum Principle is then applied to design the EMSs. Section 4 is devoted to
101 the implementation issue of the developed EMSs on an advanced dynamic vehicle simulator and the
102 analysis of the obtained results. To this end, the brief description of simulator is first given. Then, a

103 discussion on how to use the optimal control outputs and also a simple adaptation idea to obtain
 104 causal strategies from optimal ones are presented. Next, the simulation results are performed to show
 105 the effectiveness of the developed strategies. Finally, a conclusion is given in Section 5.

106 2. Vehicle Description and Control-Based Models

107 The considered vehicle architecture is depicted in Figure 1. The notations are given in **Appendix**.

108

109 Figure 1. Representation of the studied vehicle architecture

110 The vehicle is equipped with a conventional powertrain with 5-speed manual transmission. The
 111 alternator is connected to the engine with a fixed gear ratio. The only difference between the two
 112 considered case studies consists in their electric power system, i.e. the "Electric System" block in
 113 Figure 1. The power flow of both case studies is described below.

114 2.1. Case study 1: Single storage electric power system

115 The power flow in this case is sketched in Figure 2. The direction of the arrows corresponds to the
 116 direction of the energy exchange between different components.

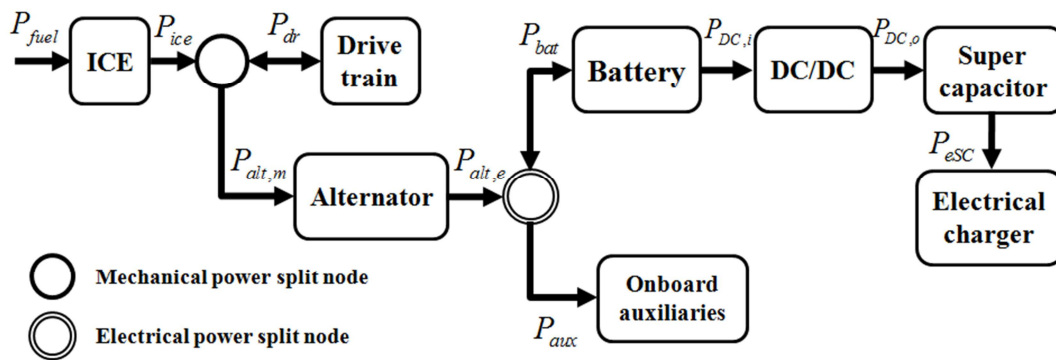

117

118 Figure 2. Power flow of the studied vehicle with single storage electric power system

119 The ICE produces the mechanical power P_{ice} from chemical energy (fuel). This mechanical power
 120 P_{ice} is divided into two parts. The first part P_{dr} is used for vehicle propulsion. The second one $P_{alt,m}$
 121 is delivered to the alternator and then converted to electrical power $P_{alt,e}$. The alternator generates the
 122 power to satisfy the demand P_{loads} of all onboard auxiliaries including the eSC. It is also used to
 123 charge the battery when necessary. The battery power P_{bat} can be negative (when it is charged by the
 124 alternator) as well as positive (when it provides electric power for all electrical loads). It should be
 125 noticed that the eSC is controlled by engine control unit (ECU) which is out of the present work
 126 scope. However, its energy consumption profile is known and will be considered as an input of the
 127 developed EMSs.

128 *2.2. Case study 2: Dual storage electric power system*

129 A sketch of the power flow in this case is depicted in Figure 3. It is worth noting that Case study 1
 130 is nothing else than a special case of Case study 2 where the supercapacitor and the DC/DC converter
 131 are removed from the electric power system.

132

133 Figure 3. Vehicle power flow in the studied dual storage electric power system

134 It can be observed that the consumption of onboard auxiliaries P_{aux} can be powered either by the
 135 alternator or by the battery. The battery is also used to charge the supercapacitor through the DC/DC
 136 converter. However, the supercapacitor cannot charge the battery in this electric structure; it is
 137 exclusively used to power the eSC.

138 2.3. *Vehicle Control-Based Model*

139 The control models are used to develop the energy optimization algorithm. At each sampling time,
140 the energy optimization algorithm computes the optimal control sequences that minimize the energy
141 consumption of the vehicle. For real-time applications, the control model should have a very limited
142 complexity. Hereafter, some control models of the components of interest for both case studies will
143 be described. It is worth noting that for confidentiality reasons with our industrial partners, all figures
144 showing the data of system components are slightly scaled so that the characteristics of these
145 components will not be revealed.

146 2.3.1. *Internal combustion engine*

147 ICE is a complex system where many physical phenomena are not easy to model, e.g. combustion
148 process [20]. However, from an energetic point of view some assumptions can be considered. Here,
149 the temperature dependency and the dynamic behavior of the ICE will be neglected. Then, ICE is
150 characterized by a static look-up-table (LUT) giving the instantaneous fuel consumption in function
151 of the engine torque and the engine speed, see Figure 4.

152

153 Figure 4. Representation of the instantaneous fuel consumption of the studied engine

154 Moreover, at a given engine speed, the engine torque is physically limited by its maximum available
155 torque. This characteristic is also represented by a static LUT.

156 2.3.2. Alternator

157 The alternator is characterized by some static LUTs as in the case of ICE. The first one, shown in
158 Figure 5, provides the alternator efficiency as a function of the rotary speed and the current. The
159 second LUT needed for the alternator average model provides the maximum current that the
160 alternator can produce as a function of the rotary speed and the current, see Figure 6.

161

162

Figure 5. Representation of the alternator efficiency

163

164

Figure 6. Representation of the alternator maximal current

165 For energy management strategy design, another LUT providing the maximum available torque at a
166 given alternator speed is also needed. This one guarantees that the alternator torque is always within

167 its physical limitation. Note that the alternator only works in generator mode, so its current is
 168 conventionally positive and is assumed to be measured for the optimization design problem.

169 2.3.3. Battery

170 For control purpose, the thermal-temperature effects of the battery are usually neglected. Then, the
 171 only state variable left in the battery is its state of charge (SOC) whose dynamics equation is given as
 172 follows:

$$173 \quad \dot{SOC}_{bat}(t) = -\frac{I_{bat}(SOC_{bat}(t))}{Q_{bat,0}}; \quad SOC_{bat}(0) = SOC_{bat,0} \quad (1)$$

174 where the initial state of charge $SOC_{bat,0}$ and the nominal capacity $Q_{bat,0}$ of the battery are given. The
 175 expression of the battery current can be given as [8]:

$$176 \quad I_{bat}(SOC_{bat}(t)) = \frac{U_{oc}(SOC_{bat}(t)) - \sqrt{U_{oc}^2(SOC_{bat}(t)) - 4R_{bat}(SOC_{bat}(t))P_{bat}(t)}}{2R_{bat}(SOC_{bat}(t))} \quad (2)$$

177 where $P_{bat}(t)$ is the battery power at the terminal voltage.

178 2.3.4. Supercapacitor

179 After neglecting all complex thermal-electrochemical dynamics, the only state variable left in the
 180 supercapacitor is its voltage U_c which is the image of its available energy amount:

$$181 \quad \dot{U}_c(t) = -\frac{I_{sc}(U_c(t))}{C_{sc}}; \quad U_c(0) = U_{c,0} \quad (3)$$

182 where the capacitance C_{sc} and the initial voltage $U_{c,0}$ of the supercapacitor are constant and given.

183 Similar to the battery, the supercapacitor current expression can be also given as:

$$184 \quad I_{sc}(U_c(t)) = \frac{U_c(t) - \sqrt{U_c^2(t) - 4R_{sc}P_{sc}(t)}}{2R_{sc}} \quad (4)$$

185 where $P_{sc}(t)$ is the supercapacitor power at the terminal voltage.

186

187 2.3.5. DC/DC converter

188 The DC/DC converter is simply modeled by the following efficiency rate:

$$189 \quad \eta_{DC} = \frac{P_{DC,o}(t)}{P_{DC,i}(t)} \quad (5)$$

190 where $P_{DC,o}(t)$ and $P_{DC,i}(t)$ are respectively converter output and input powers. The efficiency of the
191 DC/DC converter is given.

192 3. Optimal Control Based Energy Management

193 Hereafter, the optimization problem is formulated for two case studies:

- 194 • Case study 1: single storage electric power system
- 195 • Case study 2: dual storage electric power system

196 Next, the PMP will be applied to derive the energy management strategies for these both cases.

197 3.1. Problem Formulation

198 3.1.1. Control objective

199 In this work, the goal of optimal control is to minimize the fuel consumption over the driving
200 cycle in the time optimization horizon $[0, T]$, then the cost function is expressed by:

$$201 \quad \mathcal{J} = \int_0^T Q_{lhv} \dot{m}_{fuel}(T_{ice}(t), \omega_{ice}(t)) dt = \int_0^T P_{fuel}(T_{ice}(t), \omega_{ice}(t)) dt \quad (6)$$

202 where $P_{fuel}(T_{ice}(t), \omega_{ice}(t))$ is the fuel power and the instantaneous fuel consumption of ICE
203 $\dot{m}_{fuel}(T_{ice}(t), \omega_{ice}(t))$ is known at a given engine speed ω_{ice} and torque T_{ice} .

204 **Remark 1:** The pollutant emissions can be also incorporated by modifying the cost function (6) as:

$$205 \quad \tilde{\mathcal{J}} = \int_0^T \left(P_{fuel}(T_{ice}(t), \omega_{ice}(t)) + \sum_{i=1}^n \alpha_i \dot{m}_i(T_{ice}(t), \omega_{ice}(t)) \right) dt \quad (7)$$

206 where α_i are weighting factors provided by designers and the instantaneous pollutant emission rates
207 $\dot{m}_i(T_{ice}(t), \omega_{ice}(t))$ (in general NO_x , CO , HC) are given by static LUTs. However, the objective to

208 minimize the pollutant emissions is beyond the scope of this paper; therefore only the cost function
 209 of the form (6) will be considered in the sequel.

210 3.1.2. Constraints

211 *a. Vehicle architecture constraints:* The mechanical relations between torques and speeds of the
 212 considered vehicle architecture represented in Figure 1 are given by the equations:

$$213 \begin{cases} T_w(t) = R(k(t))\eta_{gb}(T_{ice}(t) + \rho T_{alt}(t)) = R(k(t))\eta_{gb}T_{ps}(t) \\ \omega_w(t) = \frac{\omega_{ice}(t)}{R(k(t))} = \frac{\omega_{alt}(t)}{\rho R(k(t))} \end{cases} \quad (8)$$

214 The driving cycle is usually defined by the couple $(\omega_w(t), k(t))$. Indeed, when $\omega_w(t)$ and $k(t)$ are
 215 known, the torque requested at the wheels $T_w(t)$ can be easily derived for the vehicle longitudinal
 216 dynamics equation [6]. In this work, engaged gear $k(t)$ at each moment is chosen by the driver.
 217 Then, it can be noticed from (8) that, with a given driving cycle, neither the engine speed nor the
 218 alternator speed can be chosen by the energy management strategy, the only degree of freedom of the
 219 studied architecture is the alternator torque (or ICE torque).

220 *b. Mechanical constraints:* Due to the physical limitations of the ICE and the alternator, their speeds
 221 and torques are subject to the following constraints:

$$222 \begin{cases} \omega_{ice,min} \leq \omega_{ice}(t) \leq \omega_{ice,max} \\ \omega_{alt,min} \leq \omega_{alt}(t) \leq \omega_{alt,max} \end{cases} \quad (9)$$

223 and

$$224 \begin{cases} T_{ice,min}(\omega_{ice}(t)) \leq T_{ice}(t) \leq T_{ice,max}(\omega_{ice}(t)) \\ T_{alt,min}(\omega_{alt}(t)) \leq T_{alt}(t) \leq T_{alt,max}(\omega_{alt}(t)) \end{cases} \quad (10)$$

225 By considering the physical alternator torque limits, the engine torque limits at each instant t are
 226 given as, where the primary shaft torque $T_{ps}(t) = T_{ice}(t) + \rho T_{alt}(t)$ is derived from the driving cycle:

$$227 T_{ice}(t) \in \mathcal{T}_{ice} = \left\{ T_{ice}(t) : \underline{T}_{ice,min}(\omega_{ice}(t)) \leq T_{ice}(t) \leq \overline{T}_{ice,max}(\omega_{ice}(t)) \right\} \quad (11)$$

228 where

$$229 \quad \begin{cases} T_{ice,\min}(\omega_{ice}(t)) = \max\{T_{ice,\min}(\omega_{ice}(t)), T_{ps}(t) - \rho T_{alt,\max}(\omega_{alt}(t))\} \\ T_{ice,\max}(\omega_{ice}(t)) = \min\{T_{ice,\max}(\omega_{ice}(t)), T_{ps}(t) - \rho T_{alt,\min}(\omega_{alt}(t))\} \end{cases} \quad (12)$$

230 *c. Electric power system constraints:* As mentioned above, the only difference between the two
 231 considered case studies consists in their energy storage systems. Case study 1 deals only with one
 232 battery, see Figure 7. The optimization problem formulation in this case is similar to the one of
 233 conventional parallel hybrid electric vehicles with only one system state of the battery (1).

234

235 Figure 7. Sketch of the electric structure of Case study 1

236 From the electric structure in Figure 7, the battery current can be computed as:

$$237 \quad I_{bat}(t) = I_{alt}(t) - I_{loads}(t) \quad (13)$$

238 where the electric load current $I_{loads}(t)$ is known and represents all onboard auxiliary demand
 239 including the consumption of eSC. The current delivered by the alternator $I_{alt}(t)$ can be easily
 240 derived from the optimal alternator torque at each time step. It is noticed from (13) that if the
 241 alternator is optimally controlled, then, the battery use is also indirectly optimized in the sense of
 242 energy efficiency.

243 For Case study 2, both battery and supercapacitor are considered. They are linked by a DC/DC
 244 converter. The electric structure of this case is depicted in Figure 8. In this case, the dynamics of the
 245 supercapacitor (3) should be considered together with (1) for optimization problem to fully take
 246 advantage of all electric structure potential.

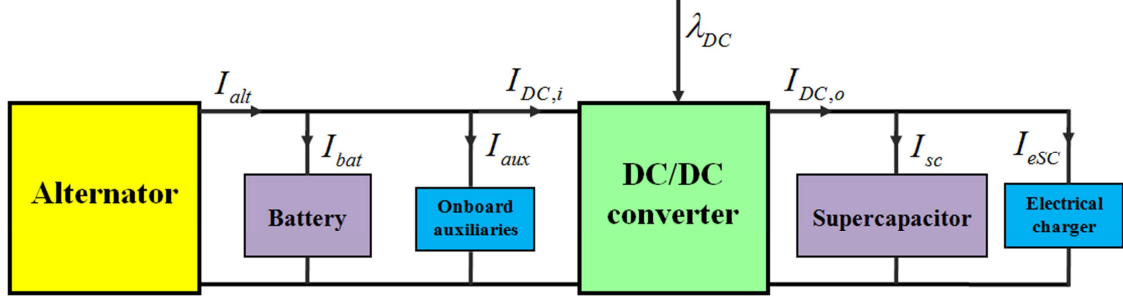

Figure 8. Sketch of the electric structure of Case study 2

In this work, the DC/DC converter controls its output current, i.e. $\lambda_{DC}(t) = I_{DC,o}(t)$. It is noticed that the electric structure of Case study 2 offers a second degree of freedom for optimization problem: the DC/DC output (or input) current. Indeed, if one of these two currents is optimized, the other can be easily deduced from the power relation (5) of DC/DC converter. The battery and supercapacitor currents are respectively computed by the following relations:

$$I_{bat}(t) = I_{alt}(t) - I_{aux}(t) - I_{DC,i}(t) \quad (14)$$

$$I_{sc}(t) = I_{DC,o}(t) - I_{eSC}(t) \quad (15)$$

The DC/DC output current is constrained by:

$$I_{DC,o}(t) \in \mathcal{I}_{DC,o} = \left\{ I_{DC,o}(t) : \underline{I}_{DC,o} \leq I_{DC,o}(t) \leq \overline{I}_{DC,o} \right\} \quad (16)$$

where $\underline{I}_{DC,o}$ and $\overline{I}_{DC,o}$ are respectively the minimum and maximum output current of the converter.

For safe operation and cycle life extension, the battery SOC and battery current are both limited:

$$SOC_{bat,min} \leq SOC_{bat}(t) \leq SOC_{bat,max} \quad (17)$$

$$I_{bat,min} \leq I_{bat}(t) \leq I_{bat,max} \quad (18)$$

For the supercapacitor, the voltage U_c and the current I_{sc} are subject to the following constraints:

$$U_{c,min} \leq U_c(t) \leq U_{c,max} \quad (19)$$

$$I_{sc,min} \leq I_{sc}(t) \leq I_{sc,max} \quad (20)$$

265 Both battery and supercapacitor are considered as energy buffer systems. Therefore, the *charge*
 266 *sustaining condition* should be fulfilled by EMS for both of them. Concretely, one should have
 267 $\Delta SOC_{bat} \approx 0$ and $\Delta U_c \approx 0$ where:

$$268 \quad \Delta SOC_{bat} \triangleq SOC_{bat}(T) - SOC_{bat}(0) \quad (21)$$

$$269 \quad \Delta U_c \triangleq U_c(T) - U_c(0) \quad (22)$$

270 3.2. Application of Pontryagin's Minimum Principle

271 Next, the PMP will be applied to the two cases. Only offline optimal solutions will be considered in
 272 this subsection. Thereafter, for simplicity, the explicit time-dependence of the variables is omitted
 273 except for confusing situations.

274 3.2.1. Case study 1: Single storage electric power system

275 Taking into account (1) and (6), the Hamiltonian in this case is defined as:

$$276 \quad \mathcal{H}(SOC_{bat}, T_{ice}, \lambda_1) = P_{fuel}(T_{ice}, \omega_{ice}) - \lambda_1 \frac{I_{bat}(SOC_{bat})}{Q_{bat,0}} \quad (23)$$

277 where the battery current $I_{bat}(SOC_{bat})$ is computed by (13). The necessary optimality conditions
 278 provided by PMP in this case are given as:

$$279 \quad \dot{SOC}_{bat}^* = \frac{\partial \mathcal{H}(\cdot)}{\partial \lambda_1} = - \frac{I_{bat}(SOC_{bat}^*)}{Q_{bat,0}}; \quad SOC_{bat}^*(0) = SOC_{bat,0} \quad (24)$$

$$280 \quad \dot{\lambda}_1^* = - \frac{\partial \mathcal{H}(\cdot)}{\partial SOC_{bat}} = \frac{\lambda_1^*}{Q_{bat,0}} \frac{\partial I_{bat}(SOC_{bat}^*)}{\partial SOC_{bat}} \quad (25)$$

$$281 \quad SOC_{bat}^*(T) \approx SOC_{bat,0} \quad (26)$$

$$282 \quad SOC_{bat,min} \leq SOC_{bat}^* \leq SOC_{bat,max} \quad (27)$$

$$283 \quad \mathcal{H}(SOC_{bat}^*, T_{ice}^*, \lambda_1^*) \leq \mathcal{H}(SOC_{bat}^*, T_{ice}, \lambda_1^*); \quad \forall t \in [0, T]; \quad \forall T_{ice} \in \mathcal{T}_{ice} \quad (28)$$

284 Several comments can be made regarding these optimality conditions. First, the conditions (24) and
 285 (25) provide respectively the dynamics of the system state and its associated co-state. However,

286 neither an initial condition nor a final condition on the co-state is available. Second, it is important to
 287 emphasize that when the charge sustaining condition guaranteed by (26) is required for the EMS, the
 288 battery usually operates only in a small range of SOC [21]. As a consequence, the open circuit
 289 voltage and the internal resistance of the battery may not vary so much in this range. Therefore, from
 290 (2), it can be concluded that the battery current $I_{bat}(SOC_{bat})$ is not significantly affected by the
 291 variation of battery SOC. Combining this fact with condition (25), it follows that:

$$292 \quad \dot{\lambda}_1 \approx 0 \Rightarrow \lambda_1 = \lambda_{10} \quad (29)$$

293 where the constant λ_{10} has to be determined. This assumption has been exploited in many other
 294 previous works [11,6,21]. Third, our studied battery has an important nominal capacity $Q_{bat,0}$, then,
 295 the state constraints (27) will never be violated. Fourth, at each instant t , the optimal control T_{ice}^*
 296 minimizing the Hamiltonian can be exhaustively searched in the torque admissible set \mathcal{T}_{ice} defined in
 297 (11). This can be numerically done by testing all torque possibilities of the set \mathcal{T}_{ice} at each time step.
 298 Hence, the constraints on the control variable T_{ice} are "naturally" considered. Fifth, it is clear that the
 299 optimal solution at each instant t depends on the initial conditions of the system state $SOC_{bat,0}$ and
 300 the co-state λ_{10} . The former initial condition is given, however, the latter one is not known *a priori*.
 301 The value of λ_{10} depends on boundary condition of the terminal cost at final time T , i.e. the future
 302 information of the driving conditions. Indeed, the determination/estimation of this value is crucial to
 303 reach the optimal solution as close as possible. For offline situations where driving cycles are given
 304 in advance, the value of λ_{10} can be iteratively computed by a "root finding algorithm" [11].

305 3.2.2. Case study 2: Dual storage electric power system

306 In this case, two dynamical systems (1) and (3) are available for the energy storage system. As
 307 previously highlighted, the state constraints (19) of the supercapacitor should be taken into account.
 308 To this end, a new dummy variable has been introduced whose dynamics is defined as [22]:

309 $\dot{X}_d \triangleq T(U_c)$ (30)

310 where the function $T(U_c)$ in (30) is defined as:

311 $T(U_c) = [U_c - U_{c,\min}]^2 \text{sg}(U_{c,\min} - U_c) + [U_{c,\max} - U_c]^2 \text{sg}(U_c - U_{c,\max})$ (31)

312 and the function $\text{sg}(\cdot)$ in (31) is given as:

313 $\text{sg}(x) \triangleq \begin{cases} 0, & x < 0 \\ 1, & x \geq 0 \end{cases}$ (32)

314 Note that $\dot{X}_d(t) \geq 0, \forall t \in [0, T]$ and $\dot{X}_d(t) = 0$ only for times when the state constraints (19) are
 315 satisfied. The new dummy variable $X_d(t)$:

316 $X_d(t) = \int_0^t \dot{X}_d(t) dt + X_d(0)$ (33)

317 is required to satisfy the two boundary conditions: $X_d(0) = 0$ and $X_d(T) = 0$. This fact implies once
 318 again that $X_d(t) = 0, \forall t \in [0, T]$. However, it is possible only if the state constraints (19) are
 319 satisfied for all $t \in [0, T]$.

320 Taking into account the dynamics (1), (3) and (30), the augmented Hamiltonian for the Case study 2
 321 is defined as follows:

322
$$\begin{aligned} \mathcal{H}_a(SOC_{bat}, U_c, T_{ice}, I_{DC,o}, \lambda_1, \lambda_2) = & P_{fuel}(T_{ice}, \omega_{ice}) - \lambda_1 \frac{I_{bat}(SOC_{bat})}{Q_{bat,0}} \dots \\ & - \lambda_2 \frac{I_{sc}(U_c, I_{DC,o})}{C_{sc}} + \lambda_d T(U_c) \end{aligned}$$
 (34)

323 Then, the necessary optimality conditions are given by (24)-(27) together with the following ones:

324 $\dot{U}_c^* = \frac{\partial \mathcal{H}_a(\cdot)}{\partial \lambda_2} = -\frac{I_{sc}(U_c^*, I_{DC,o}^*)}{C_{sc}}; \quad U_c^*(0) = U_{c,0}$ (35)

325 $U_c^*(T) \approx U_{c,0}$ (36)

326 $U_{c,\min} \leq U_c^* \leq U_{c,\max}$ (37)

$$\begin{aligned}
327 \quad \dot{X}_d^* &= \frac{\partial \mathcal{H}_a(\cdot)}{\partial \lambda_d} = [U_c^* - U_{c,\min}]^2 \text{sg}(U_{c,\min} - U_c^*) + [U_{c,\max} - U_c^*]^2 \text{sg}(U_c^* - U_{c,\max}) \\
X_d^*(0) &= 0
\end{aligned} \tag{38}$$

$$\begin{aligned}
328 \quad \dot{\lambda}_2^* &= -\frac{\partial \mathcal{H}_a(\cdot)}{\partial U_c} = \frac{\lambda_1^*}{Q_{bat,0}} \frac{\partial I_{bat}(SOC_{bat}^*)}{\partial U_c} + \frac{\lambda_2^*}{C_{sc}} \frac{\partial I_{sc}(U_c^*, I_{DC,o}^*)}{\partial U_c} \dots \\
&\quad - 2\lambda_d^* [U_c^* - U_{c,\min}] \text{sg}(U_{c,\min} - U_c^*) - 2\lambda_d^* [U_{c,\max} - U_c^*] \text{sg}(U_c^* - U_{c,\max})
\end{aligned} \tag{39}$$

$$329 \quad \dot{\lambda}_d^* = -\frac{\partial \mathcal{H}_a(\cdot)}{\partial X_d} \tag{40}$$

$$\begin{aligned}
330 \quad \mathcal{H}_a(SOC_{bat}^*, U_c^*, T_{ice}^*, I_{DC,o}^*, \lambda_1^*, \lambda_2^*, \lambda_d^*) &\leq \mathcal{H}_a(SOC_{bat}^*, U_c^*, T_{ice}^*, I_{DC,o}^*, \lambda_1^*, \lambda_2^*, \lambda_d^*); \\
\forall t \in [0, T]; \quad \forall (T_{ice}^*, I_{DC,o}^*) &\in \mathcal{T}_{ice} \times \mathcal{I}_{DC,o}
\end{aligned} \tag{41}$$

331 As in Case study 1, $\lambda_1 = \lambda_{10}$, $\forall t \in [0, T]$ and at each instant t , the optimal control inputs $T_{ice}^*(t)$ and
332 $I_{DC,o}^*(t)$ minimizing the Hamiltonian can be exhaustively searched in the torque and current
333 admissible sets \mathcal{T}_{ice} and $\mathcal{I}_{DC,o}$ defined respectively in (11) and (16).

334 Since X_d does not appear explicitly in $\mathcal{H}_a(\cdot)$, then, it can be deduced from (40) that:

$$335 \quad \dot{\lambda}_d^* = -\frac{\partial \mathcal{H}_a(\cdot)}{\partial X_d} = 0 \Rightarrow \lambda_d^* = \lambda_{d0} \tag{42}$$

336 where λ_{d0} is the constant to be determined. Note that if the supercapacitor has an important
337 capacitance C_{sc} , its state constraints (19) will be then trivial. In this case, λ_{d0} can be set equal to 0,
338 which means that the supercapacitor state constraints are not taken into account.

339 From the supercapacitor current $I_{sc}(U_c)$ expression in (4), it follows that:

$$340 \quad \frac{\partial I_{sc}(U_c)}{\partial U_c} = -\frac{I_{sc}(U_c)}{\sqrt{U_c^2 - 4R_{sc}P_{sc}}} \tag{43}$$

341 Then, the condition (39) can be rewritten as:

$$\lambda_2^* = \frac{-\lambda_2^* I_{sc}(U_c^*)}{C_{sc} \sqrt{(U_c^*)^2 - 4R_{sc} P_{sc}}} \dots \quad (44)$$

$$-2\lambda_{d0} [U_c^* - U_{c,\min}] \operatorname{sg}(U_{c,\min} - U_c^*) - 2\lambda_{d0} [U_{c,\max} - U_c^*] \operatorname{sg}(U_c^* - U_{c,\max})$$

343 The trajectory λ_2^* is obtained by integrating both sides of (44) which $\lambda_2^*(0) = \lambda_{20}$ has to be
 344 determined.

345 The optimization problem of Case study 2 is now reduced to the choice of the three values λ_{10} ,
 346 λ_{20} and λ_{d0} in such a manner that both boundary conditions (charge sustaining conditions) (26) and
 347 (36) are satisfied. However, using a "root finding algorithm" as in Case study 1 to iteratively compute
 348 these three values would not be appropriate due to excessive computation times. A simple method,
 349 which is more effective in terms of computation times, will be proposed latter. Although this method
 350 only offers sub-optimal control sequences of T_{ice}^* and $I_{DC,o}^*$, it can be directly used for online
 351 implementation.

352 3.2.3. Physical interpretation of Hamiltonian

353 This subsection aims at pointing out the physical meaning of the Hamiltonians and the co-states in
 354 the previous definitions (23) and (34). To this end, only Hamiltonian of Case study 2 is considered
 355 since it is of a more general form than the one in (23).

356 Let us define the following variables:

$$s_1 \triangleq -\frac{\lambda_1}{U_{oc}(SOC_{bat})Q_{bat,0}}; \quad s_2 \triangleq -\frac{\lambda_2}{U_c C_{sc}} \quad (45)$$

358 Then, the expression of the Hamiltonian in (34) can be rewritten as:

$$\mathcal{H}_a(SOC_{bat}, U_c, T_{ice}, I_{DC,o}, s_1, s_2) = P_{fuel}(T_{ice}, \omega_{ice}) + s_1 P_{bat,i}(SOC_{bat}) \dots \quad (46)$$

$$+ s_2 P_{sc,i}(U_c, I_{DC,o}) + \lambda_d T(U_c)$$

360 where $P_{fuel}(T_{ice}, \omega_{ice})$, $P_{bat,i}(SOC_{bat})$ and $P_{sc,i}(U_c, I_{DC,o})$ are respectively the fuel power, the inner
 361 battery power and the inner supercapacitor power. The physical meaning of the Hamiltonian becomes

362 clearer with (46). Indeed, this is the sum of the weighted powers of all energy sources available in the
363 vehicle. In other words, the Hamiltonian represents an *equivalent fuel power*; and the variables s_1
364 and s_2 are used to convert the inner battery power and the inner supercapacitor power into the
365 equivalent quantities of fuel power. That is why these variables are usually referred to *equivalence*
366 *factors* [13,14]. The more important these variables are, the more expensive the electric energy is. So,
367 it is more beneficial to recover the energy by regenerative braking. On the contrary, the lower these
368 variables are, the cheaper the electric energy is also. As a consequence, it is more beneficial to use the
369 electric machine to generate the energy (for the case of hybrid vehicles).

370 In the cases where the state constraints are present, the dynamics \dot{X}_d indicates these constraints
371 are whether or not violated. Then, the term $\lambda_d \dot{X}_d = \lambda_{d0} \dot{X}_d$ is incorporated into the Hamiltonian as a
372 penalty function. The constant λ_{d0} should be selected to be very high such that the supercapacitor
373 state lies in its bound limits in very short time. Since there is no penalty if the state remains between
374 its upper and lower limits, the energy management strategies can make full use of the supercapacitor
375 over the allowable range.

376 **4. Implementation and Results Analysis**

377 *4.1. Dynamic Vehicle Simulator*

378 Before analyzing the results, it should be noticed that all developed strategies in this work are
379 validated with a dynamic vehicle simulator calibrated with real vehicle data. This simulator consists
380 of all appropriate models of different elements constituting the studied vehicle, including the driver
381 and the energy management strategy. An overview of the simulation environment in this work is
382 illustrated in Figure 9. As can be seen, the considered simulation environment has two separated
383 parts: the vehicle model part and the energy management system part.

384

385

395

396

397

398

The energy management system part is our optimization algorithm coded in C-language for time computation efficiency and implemented in Matlab/Simulink as an S-function. The vehicle model part accurately represents all relevant characteristics of the real vehicle. This one is implemented in LMS Imagine.Lab AMESim platform which is inspired by Bond Graph approach [23]. The model and control strategies involved of this dynamic vehicle simulator have been developed by our industrial partners and will not be exposed here for confidentiality. The two parts of the simulation environment are interconnected by a co-simulation interface. The most advantage of this simulation approach is that it offers at the same time the realistic vehicle model and the great convenience of Matlab/Simulink in terms of control design.

In what follows, some issues directly related to the implementation of the developed energy management strategies into the simulator are first discussed. Next, a simple idea to derive a causal EMS for real-time applications is presented. Then, to show the performance of the developed strategies in terms of energy consumption efficiency, they will be also compared to a baseline

399 strategy where the energy storage system (ESS: battery and/or supercapacitor) will be practically
 400 never charged or discharged. As a consequent, the alternator will be always activated to generate all
 401 energy needed for onboard electric demand. Note also that these baseline strategies, provided by our
 402 industrial partners, will not be detailed for confidentiality reason.

403 4.2. Implementation

404 4.2.1. How to use the optimal control sequences?

405 The developed EMSs provide the engine torque and also the alternator torque in both case studies.
 406 They are often used as reference signals to control the ICE and the alternator, respectively. However,
 407 in this project, the ECU is designed by another industrial partner and only optimal alternator torque
 408 T_{alt}^* will be used to control the reference voltage of the alternator. The control scheme of the
 409 alternator is illustrated in Figure 10.

410
 411 Figure 10. Control scheme of the alternator

412 For Case study 2, the EMS provides also the optimal control sequence $I_{DC,o}^*$ which will be used to
 413 control the DC/DC converter as shown in Figure 8.

414 It is important to remark that the approach used in our work does not require any modifications of
 415 the vehicle structure (drive train and electric power system). The only simple task for implementation
 416 is to replace the existing controller(s) of the baseline strategy with those developed in this paper.

417 4.2.2. Online adaptation

418 As previously emphasized, it is possible to obtain the optimal solutions only when all information
 419 of the entire driving cycle is available *a priori*. In subsection 3.2, we also showed that the

420 optimization problems consist finally in determining the constant λ_{10} for Case study 1 and constants
421 λ_{10} and λ_{20} for Case study 2 with a "root finding algorithm". However, these strategies are not causal
422 and cannot be applicable for real-world applications. Therefore, an adaptation of these strategies for
423 online implementation is necessary. Over the years, a great deal of efforts has been investigated to
424 cope with online strategies based on non-causal optimal ones [6]. The crucial point of this problem is
425 to find out an appropriate way to adapt the co-state(s) in such a manner that the behavior of causal
426 strategies is as close as possible to the corresponding optimal solution. For simplicity and for
427 computation efficiency, the so-called " λ -control" method is adopted in this work [24,25,10]. This
428 method is based on a feedback control which is easy to implement, see Figure 11. The expression of
429 the estimated $\tilde{\lambda}$ is given as:

$$430 \quad \tilde{\lambda} = \lambda_0 + K_p (SOC_{sp} - SOC) + K_i \int_0^t (SOC_{sp} - SOC) \quad (47)$$

431 where SOC_{sp} is the SOC set point of the considered energy system storage. This value is given as
432 $SOC_{sp} = SOC(0)$ if the charge sustaining condition is considered. K_p , K_i are the gains of the PI
433 controller and λ_0 is the initial guess.

434

435 Figure 11. Online estimation of the co-state $\tilde{\lambda}$

436 It can be noticed that the idea of the " λ -control" method is simply to keep the SOC of each
437 energy storage system in a reference range of variation defined by SOC_{sp} . In other words, the
438 feedback " λ -control" aims at preventing the overcharge or depletion of the considered ESS in long

439 term, however, its SOC may "freely" vary in short term. For this reason, the PI controller gains
440 should be selected rather low. A detail on this discussion can be found in [25].

441 4.3. Simulation Results

442 In this work, the Artemis Road cycle [26] will be exclusively considered to validate the different
443 energy management strategies. This driving cycle represents real driving conditions and allows
444 achieving a realistic evaluation of the obtained results. The vehicle speed and gear position of this
445 real-world driving cycle are shown in Figure 12. For all simulations presented hereafter, the tracking
446 performance of the vehicle with respect to the speed reference of the considered driving cycle is
447 always perfectly guaranteed.

448

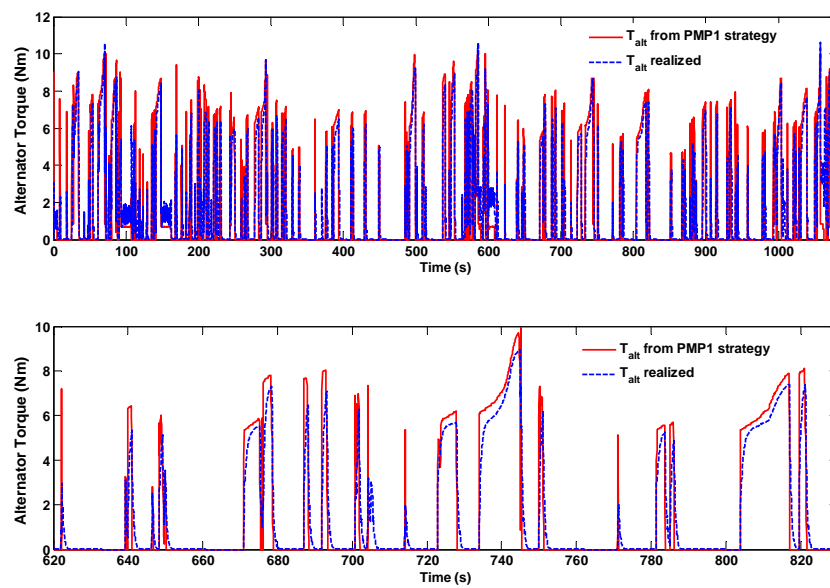

449 Figure 12. Artemis Road cycle: vehicle speed (up) and imposed gearbox ratio (bottom)

450 4.3.1. Case study 1

451 The following strategies are implemented and their results will be compared:

- 452 • BL1: Baseline strategy for Case study 1 where the battery is not practically used, so the
453 alternator power is almost equal to the required electric load.
- 454 • PMP1: PMP-based optimal strategy for Case study 1 with a given driving cycle.
- 455 • RT1: Real-time strategy for Case study 1 with $\tilde{\lambda}_1$ estimated by (47).

456 The desired and the realized alternator torques obtained from PMP1 strategy are presented in
 457 Figure 13. It can be noticed that the alternator torque, which is indirectly imposed by the voltage
 458 reference of the electric power system, globally tracks the optimal alternator torque provided by the
 459 PMP1 strategy. However, the alternator has its own dynamics. Hence, the realized torque tends to 0
 460 after a certain time for each alternator activation. This problem, which is unavoidable, will degrade
 461 the fuel saving performance of the PMP1 strategy. Indeed, the alternator can take some electric
 462 energy which is unscheduled by PMP1 strategy.

463

464 Figure 13. Optimal alternator torque provided by PMP1 strategy and real alternator provided by
 465 simulator for all the driving cycle (up) and their zooms (bottom)

466 Figure 14 shows the comparison of realized alternator torques between PMP1 and BL1 strategies. As
 467 previously stated, BL1 tries to maintain a constant alternator voltage; such that the battery is
 468 practically not used and all onboard electric load energy is directly supplied by the alternator. Hence,
 469 the alternator will be always activated for this strategy and this can increase the fuel consumption.
 470 Concerning PMP1 strategy, it schedules the alternator activation at appropriate moments
 471 (deceleration phases, battery charging) and with appropriate quantities of torque. In such a manner,
 472 PMP1 strategy can help to recover a certain amount of "free energy" coming from regenerative
 473 braking. In addition, with this optimal strategy, the alternator can be also used to shift the operating

474 point of the ICE to other regions that require relative less fuel. Moreover, the battery will be better
 475 exploited as shown in Figure 15.

476

477 Figure 14. Comparison of realized alternator torques between BL1 and PMP1 strategies

478

479 Figure 15. Battery state of charge for different strategies (up); trajectory of estimated $\tilde{\lambda}_1$
 480 corresponding to RT1 strategy (bottom)

481 From Figure 15, it can be observed that if the co-state $\tilde{\lambda}_1$ is fine tuned then RT1 strategy has the same
 482 behaviors as PMP1 strategy although it does not need any information on the future of driving cycle.

483 Table 1 summarizes the energy consumption of the considered strategies and the fuel saving of PMP1

484 and RT1 strategies with respect to BL1 strategy for Artemis Road cycle. This table shows that the
 485 proposed strategies (OPTI1 and RT1) are not only effective to reduce the fuel consumption but also
 486 can guarantee the sustaining charge condition of the battery.

Strategy	Fuel Use [g]	Fuel Saving [%]	ΔSOC_{bat} [%]
BL1	700.072	0	0.361
OPTI1	685.597	2.068	0.056
RT1	685.776	2.042	0.111

487 Table 1. Summary of energy consumption for different strategies of Case study 1

488 4.3.2. Case study 2

489 As previously stated, searching offline optimal solution with "root finding algorithm" can be too
 490 expensive in terms of simulation time. Hence, this will be not presented here and only two strategies
 491 are implemented and compared in this case:

- 492 • BL2: Baseline strategy for Case study 2 uses only the supercapacitor. The DC/DC converter
 493 is controlled by a heuristic strategy of industrial partner. This strategy aims at guaranteeing
 494 that the voltage in the supercapacitor side is always superior to the one in the battery side and
 495 the supercapacitor energy is always kept between certain levels.
- 496 • RT2: Real-time strategy for Case study 2 with $\tilde{\lambda}_1$ and $\tilde{\lambda}_2$ estimated by (47).

497 The results of BL2 and RT2 strategies are compared in Figure 16. The same comments on the
 498 alternator activation can be done as in Case study 1, i.e. the alternator is mostly activated by RT2
 499 strategy to recover regenerative braking energy. Moreover, RT2 strategy also activates the DC/DC
 500 converter more often than BL2 strategy to charge the supercapacitor at appropriate moments. As a
 501 consequent, both energy storage systems (ESS) are better exploited in RT2 strategy than in BL2
 502 strategy as shown in Figure 17.

503

504 Figure 16. Comparison of alternator torque and converter current between BL2 and RT2 strategies

505 It can be also observed from Figure 17 that the charge sustaining conditions for both ESSs are
 506 guaranteed by RT2 strategy whereas BL2 strategy cannot fulfill this condition for the supercapacitor.

507 Indeed, BL2 strategy only has tendency to charge the supercapacitor. Moreover, as previously stated,
 508 the use of the battery is very limited in this case; in particularly the battery SOC with BL2 strategy is
 509 almost constant for the entire driving cycle.

510

511 Figure 17. Comparison of ESS state of charges between BL2 and RT2 strategies

512 Figure 18 shows that supercapacitor voltage always remains in its operating range, i.e. it is always
 513 higher than the battery voltage as imposed by the electric power system and lower than the
 514 supercapacitor voltage maximal value (16.2V). Thanks to the penalty function $\lambda_d \dot{X}_d = \lambda_{d0} \dot{X}_d$
 515 incorporated into the Hamiltonian, the supercapacitor voltage only touches its upper limit for a very
 516 short time (around 100s) of the driving cycle.

517

518 Figure 18. Voltages of energy storage systems for RT2 strategy

519 Table 2 summarizes the energy consumption of both strategies, and the fuel saving of RT2 strategy
 520 with respect to BL2 strategy for Artemis Road cycle. From the results, it can be concluded that the
 521 RT2 strategy is effective for fuel consumption reduction.

Strategy	Fuel Use [g]	Fuel Saving [%]	ΔSOC_{bat} [%]	ΔSOC_{sc} [%]
BL2	701.819	0	0.019	9.394
RT2	690.322	1.634	0.076	0.054

522 Table 2. Summary of energy consumption for different strategies of Case study 2

523 As can be seen, the results obtained on this unique cycle are very promising. However, several
 524 tests with other driving cycles would be necessary to show that the extra energy consumption of eSC

525 would be compensated with some effective energy management strategies (note that the eSC is
526 practically only activated in low load region).

527 **5. Concluding Remarks**

528 In this work, PMP-based strategies are developed to "optimally" control the vehicular electric
529 power systems. We have shown that this approach has several advantages for real-time
530 implementation. First, causal strategies, which can mimic the behavior of optimal solution, can be
531 easily obtained with a simple feedback control scheme. Second, it is very efficient in terms of time
532 computation because it is based on the instantaneous minimization of the Hamiltonian. The
533 effectiveness of the approach is pointed out through several simulation results for both case studies.
534 Most of fuel saving comes from regenerative braking which is "free" energy. Despite the additional
535 cost for hardware investments, the dual storage electric power system offers a limited fuel saving
536 performance compared to single storage electric power system for the given parameter values in the
537 simulator AMESim. However, this electric structure may be used to reduce the capacity of the battery
538 since it is not practically used or it would be more interesting for electric hybrid vehicles with "stop
539 and start" operation.

540 The energy management problem considered in this work can be directly applied to parallel hybrid
541 electric vehicles. They are also easily generalized to others hybrid architectures with some slight
542 modifications.

551

552 **Appendix.** Some notations of vehicle variables used in this paper

Variable	Description	Unit	Variable	Description	Unit
T_w	Wheel torque	Nm	ω_w	Wheel speed	rpm
T_{ice}	ICE torque	Nm	ω_{ice}	ICE speed	rpm
T_{alt}	Alternator torque	Nm	ω_{alt}	Alternator speed	rpm
T_{ps}	Primary shaft torque	Nm	ρ	Gear ratio of the reducer	--
η_{gb}	Gearbox efficiency	--	k	k^h gear of the gearbox	--
Q_{lHV}	Constant fuel energy density	kJ/kg	$R(k)$	Gearbox ratio of the k^{th} gear	--
